MARTIN'S CONJECTURE, ARITHMETIC EQUIVALENCE, AND COUNTABLE BOREL EQUIVALENCE RELATIONS

ANDREW MARKS, THEODORE SLAMAN, AND JOHN STEEL

ABSTRACT. There is a fascinating interplay and overlap between recursion theory and descriptive set theory. A particularly beautiful source of such interaction has been Martin's conjecture on Turing invariant functions. This longstanding open problem in recursion theory has connected to many problems in descriptive set theory, particularly in the theory of countable Borel equivalence relations.

In this paper, we shall give an overview of some work that has been done on Martin's conjecture, and applications that it has had in descriptive set theory. We will present a long unpublished result of Slaman and Steel that arithmetic equivalence is a universal countable Borel equivalence relation. This theorem has interesting corollaries for the theory of universal countable Borel equivalence relations in general. We end with some open problems, and directions for future research.

1. INTRODUCTION

1.1. Martin's conjecture. Martin's conjecture on Turing invariant functions is one of the oldest and deepest open problems on the global structure of the Turing degrees. Inspired by Sacks' question on the existence of a degree-invariant solution to Post's problem [21], Martin made a sweeping conjecture that says in essence, the only nontrivial definable Turing invariant functions are the Turing jump and its iterates through the transfinite.

Our basic references for descriptive set theory and effective descriptive set theory are the books of Kechris [14] and Sacks [22]. Let \leq_T be Turing reducibility on the Cantor space 2^ω , and let \equiv_T be Turing equivalence. Given $x \in 2^\omega$, let x' be the Turing jump of x . The Turing degree of a real $x \in 2^\omega$ is the \equiv_T equivalence class of x . A *Turing invariant function* is a function $f : 2^\omega \rightarrow 2^\omega$ such that for all reals $x, y \in 2^\omega$, if $x \equiv_T y$, then $f(x) \equiv_T f(y)$. The Turing invariant functions are those which induce functions on the Turing degrees.

With the axiom of choice, we can construct many pathological Turing invariant functions. Martin's conjecture is set in the context of $\text{ZF} + \text{DC} + \text{AD}$, where AD is the axiom of determinacy. We assume $\text{ZF} + \text{DC} + \text{AD}$ for the rest of this section. The results we will discuss all "localize" so that the assumption of AD essentially amounts to studying definable functions assuming definable determinacy, for instance, Borel functions using Borel determinacy.

To state Martin's conjecture, we need to recall the notion of Martin measure. A *Turing cone* is a set of the form $\{x : x \geq_T y\}$. The real y is said to be the *base* of

The results in Section 3 form part of the PhD thesis of the first author, which was done under the supervision of Ted Slaman. The first author would also like to thank Ben Miller for helpful conversations. The research of the second author was partially supported by NSF award DMS-1001551. The research of the third author was partially supported by NSF award DMS-0855692.

the cone $\{x : x \geq_T y\}$. A *Turing invariant set* is a set $A \subseteq 2^\omega$ that is closed under Turing equivalence: for all $x, y \in 2^\omega$, if $x \in A$ and $x \equiv_T y$, then $y \in A$. Martin has shown that under AD, every Turing invariant set A either contains a Turing cone, or is disjoint from a Turing cone [19]. Note that the intersection of countably many cones contains a cone; the intersection of the cones with bases $\{y_i\}_{i \in \omega}$ contains the cone whose base is the join of the y_i . Hence, under AD, the function

$$\mu(A) = \begin{cases} 1 & \text{if } A \text{ contains a Turing cone} \\ 0 & \text{if the complement of } A \text{ contains a Turing cone} \end{cases}$$

is a measure on the σ -algebra of Turing invariant sets. This measure is called Martin measure. For the rest of this section, by a.e. we will mean almost everywhere with respect to Martin measure. Since we will care only about the behavior of functions a.e., we will occasionally deal with functions which are only defined a.e.

For Turing invariant $f, g : 2^\omega \rightarrow 2^\omega$, let $f \leq_m g$ if and only if $f(x) \leq_T g(x)$ a.e. Similarly, $f \equiv_m g$ if and only if $f(x) \equiv_T g(x)$ a.e. Say that f is increasing a.e. if $f(x) \geq_T x$ a.e. Finally, say that f is constant a.e. if there exists a $y \in 2^\omega$ such that $f(x) \equiv_T y$ a.e. (i.e. the induced function on Turing degrees is constant a.e.).

We are now ready to state Martin's conjecture on Turing invariant functions.

Conjecture 1.1 (Martin [15, p. 281]). *Assume ZF + DC + AD. Then*

- I. *If $f : 2^\omega \rightarrow 2^\omega$ is Turing invariant, and f is not increasing a.e. then f is constant a.e.*
- II. *\leq_m prewellorders the set of Turing invariant functions which are increasing a.e. If f has \leq_m -rank α , then f' has \leq_m -rank $\alpha + 1$, where $f'(x) = f(x)'$ for all x .*

While Martin's conjecture remains open, significant progress has been made towards establishing its truth. Let φ_i be the i th partial recursive function. Say that $x \geq_T y$ via i if $\varphi_i(x) = y$. Say that $x \equiv_T y$ via (i, j) if $x \geq_T y$ via i and $y \geq_T x$ via j . Suppose that f is a Turing invariant function. Say that f is *uniformly Turing invariant* if there exists a function $u : \omega^2 \rightarrow \omega^2$ so that if $x \equiv_T y$ via (i, j) , then $f(x) \equiv_T f(y)$ via $u(i, j)$. Note that our definition of a uniformly Turing invariant function is slightly different than the definitions of some of the papers we reference¹.

¹ In particular, the definition of uniformly Turing invariant that we give here is different than the definitions used in [25] and [26] (which also differ from each other). The definition in [25] requires only that there is a pointed perfect tree T and a function $u : \omega^2 \rightarrow \omega^2$ such that for all $x, y \in [T]$, if $x \equiv_T y$ via (i, j) , then $f(x) \equiv_T f(y)$ via $u(i, j)$. This definition is related to our definition in the following way:

Proposition. *Let f be Turing invariant. Then there exists a uniformly Turing invariant g (using our definition) which is defined a.e. such that $g \equiv_m f$ if and only if there is a pointed perfect tree T and a function $u : \omega^2 \rightarrow \omega^2$ such that for all $x, y \in [T]$, if $x \equiv_T y$ via (i, j) , then $f(x) \equiv_T f(y)$ via $u(i, j)$.*

Proof. For the forward direction, consider the function π which maps x to the lexicographically least (i, j) such that $f(x) \equiv_T g(x)$ via (i, j) . Now use Lemma 3.5 to find a pointed perfect set on which π is constant.

For the reverse direction, first let $[T]$ be the pointed perfect set on which f is uniform. Pass to a uniformly pointed perfect tree $\hat{T} \subseteq T$ where there exists an ϵ such that for all $x \in [\hat{T}]$, we have $\varphi_\epsilon(x) = \hat{T}$. Now define the uniformly Turing invariant g by composing f with the canonical homeomorphism from 2^ω to $[\hat{T}]$, and then restricting to the cone $\{x : x \geq_T \hat{T}\}$. \square

The first progress on Martin's conjecture was made by Steel [26] and was continued by Slaman and Steel [25]. They proved that Martin's conjecture is true when restricted to the class of uniformly Turing invariant functions.

Theorem 1.2 (Slaman and Steel [25]). *Part I of Martin's conjecture holds for all uniformly Turing invariant functions.*

Theorem 1.3 (Steel [26]). *Part II of Martin's conjecture holds for all uniformly Turing invariant functions.*

Theorems 1.2 and 1.3 also imply that Martin's conjecture is true when restricted to the larger class of functions f so that $f \equiv_m g$ for some uniformly Turing invariant g . Steel has conjectured that this is true of all Turing invariant functions.

Conjecture 1.4 (Steel [26]). *If $f : 2^\omega \rightarrow 2^\omega$ is Turing invariant, then there exists a uniformly Turing invariant g which is defined a.e., and $f \equiv_m g$.*

Assuming Conjecture 1.4, Steel [26] has computed the \leq_m -rank of many familiar such jump operators. Steel also proves that Conjecture 1.4 implies that if $f(x) \in L[x]$ a.e., then f has a natural normal form in terms of master codes in Jensen's J.

The original intent of Martin's conjecture was to be a precise way of stating that the only definable non-constant Turing invariant functions are the Turing jump and its transfinite iterates such as $x \mapsto x^{(\alpha)}$ for $\alpha < \omega_1$, $x \mapsto \mathcal{O}^x$, and $x \mapsto x^\sharp$. Becker has shown that Conjecture 1.4 precisely captures this idea. In [2], Becker defines the notion of a reasonable pointclass, and shows that for any such reasonable pointclass Γ , for every x , there is a universal $\Gamma(x)$ set, where $\Gamma(x)$ is the relativization of Γ to x . (Such a universal set is not unique, but the universal $\Gamma(x)$ subset of ω will be unique up to Turing equivalence.) For instance, if we consider the pointclass of Π_1^1 sets, the universal $\Pi_1^1(x)$ subset of ω is \mathcal{O}^x . Becker has shown that the strictly increasing uniformly Turing invariant functions are precisely the functions which map x to the universal $\Gamma(x)$ subset of ω for some reasonable pointclass Γ .

Theorem 1.5 (Becker [2]). *Let $f : 2^\omega \rightarrow 2^\omega$ be a Turing invariant function so that $f(x) \geq_T x$ a.e. Then f is uniformly Turing invariant if and only if there is a reasonable pointclass Γ , and a Turing invariant g so that $g(x)$ is the universal $\Gamma(x)$ subset of ω , and $f \equiv_m g$.*

Suppose f is Turing invariant. Then say that f is *order preserving* if $x \geq_T y$ implies that $f(x) \geq_T f(y)$. Say that f is *uniformly order preserving* if there exists a function $u : \omega \rightarrow \omega$ so that $x \geq_T y$ via i implies $f(x) \geq_T f(y)$ via $u(i)$. It is clear that if f is uniformly order preserving then f is uniformly Turing invariant. A corollary of Becker's work is that for any Turing invariant f , there exists a uniformly Turing invariant g so that $g \equiv_m f$ if and only if there exists a uniformly order preserving h so that $h \equiv_m f$.

Two more cases of Martin's conjecture are known. They are especially interesting because they do not require uniformity assumptions.

Similar techniques along with Theorem 1.2 can be used to show that for all Turing invariant f , there exists a $g \equiv_m f$ that is uniformly Turing invariant in our sense if and only if there exists an $h \equiv_m f$ that is uniformly Turing invariant in the sense of [26] (where g and h are both defined a.e.).

Thus, the differences between these definitions are harmless; we have not changed what it means for a function on Turing degrees to be represented a.e. by a uniformly invariant function. We use our definition because of its simplicity, and because it generalizes in Section 3.1 more readily than the definitions of [26] and [25].

Theorem 1.6 (Slaman and Steel [25]). *If f is a Borel order preserving Turing invariant function that is increasing a.e., then there exists an $\alpha < \omega_1$ so that $f(x) \equiv_T x^{(\alpha)}$ a.e.*

The proof of this theorem uses a generalization of the Posner-Robinson theorem for iterates of the Turing jump up through ω_1 . To generalize this theorem beyond the Borel functions, it would be enough to generalize the Posner-Robinson theorem further through the hierarchy of jump operators. For instance, Woodin [33] has proved a generalization of the Posner-Robinson theorem for the hyperjump. This can be used to show that if f is increasing and order preserving a.e., and not Borel, then $f(x) \geq_T \mathcal{O}^x$ a.e.

The last known case of Martin's conjecture is for all recursive functions.

Theorem 1.7 (Slaman and Steel [25]). *Suppose $f(x) \leq_T x$ a.e. Then either $f(x) \equiv_T x$ a.e., or f is constant a.e.*

The proof of this theorem uses both game arguments and a significant amount of recursion theory. Generalizing this theorem past the Δ_1^0 functions appears to be difficult, and the proof does not give much of an idea of how to do this.

The special case of a degree invariant solution to Post's problem has also received considerable attention. Lachlan [16] has shown that there are no uniform solutions to Post's problem. This result predated Theorem 1.3, which generalized it. Downey and Shore [8] later put further restrictions on any possible solution. By using Theorem 1.3, they showed that any degree invariant solution to Post's problem must be low₂ or high₂. On the positive side, Slaman and Steel (unpublished) have proved that there is a degree invariant solution to Post's problem restricted to the domain of Σ_3^0 sets. Finally, Lewis has constructed a degree invariant solution to Post's problem on a set of sufficiently generic degrees [17].

Martin's conjecture has also inspired a couple theorems for functions from 2^ω to $P(2^\omega)$. Steel [26] has proved the existence of a natural prewellorder on inner model operators using the uniform case of Martin's conjecture. Slaman [24] has proved an analogue of Martin's conjecture for all Borel functions from 2^ω to $P(2^\omega)$ satisfying certain natural closure conditions. This proof uses a technique that is reminiscent of Theorem 1.6, and relies on a sharpening of the generalized Posner-Robinson theorem due to Shore and Slaman [23].

The metamathematics of Martin's conjecture has been the source of some interesting results. Chong and Yu [5] have constructed uniformly Turing invariant Π_1^1 counterexamples to Martin's conjecture when the hypothesis of ZF + DC + AD is replaced with ZFC + V = L. They raised the question of the consistency strength of Theorem 1.3. Chong, Wang, and Yu [4] have proved that the restriction of Theorem 1.3 to Π_{2n+1}^1 functions is equivalent to Σ_{2n+2}^1 determinacy for all $n \geq 0$.

Next, we will turn to applications of the above in the field of countable Borel equivalence relations. In this context, we will only need the restriction of Martin's conjecture to Borel functions. In what follows, when we assume Martin's conjecture, we will really mean that we assume its consequences for Borel functions. The following characterization of Borel Martin's conjecture is an easy consequence of Theorems 1.2 and 1.3.

Theorem 1.8 (Slaman and Steel). *The following are equivalent:*

- (1) *Martin's conjecture restricted to Borel functions.*

- (2) If f is Borel and Turing invariant, then either f is constant a.e., or there is an ordinal $\alpha < \omega_1$ so that $f(x) \equiv_T x^{(\alpha)}$ a.e.
- (3) If f is Borel and Turing invariant, then there exists a uniformly Turing invariant g such that $f \equiv_m g$.

Assuming Martin's conjecture, there is a particular fact about Turing invariant functions that we will use several times. Given any subset A of 2^ω , the \equiv_T -saturation of A is defined to be the smallest Turing invariant set containing it. Let $f : 2^\omega \rightarrow 2^\omega$ be a countable-to-one function that is Turing-invariant. Then the \equiv_T -saturation of $\text{ran}(f)$ must contain a Turing cone. This is because f cannot be constant a.e. and so it must be that $f(x) \geq_T x$ a.e. Hence, the complement of the \equiv_T -saturation of $\text{ran}(f)$ cannot contain a Turing cone.

1.2. Countable Borel equivalence relations. Turing equivalence is an example of a countable Borel equivalence relation. A *Borel equivalence relation* is an equivalence relation E on a Polish space X that is Borel as a subset of $X \times X$. A Borel equivalence relation is said to be *countable* if all its equivalence classes are countable.

Suppose E and F are Borel equivalence relations on the Polish spaces X and Y respectively, and $f : X \rightarrow Y$ is a function. f is said to be a *homomorphism* from E to F if for all $x, y \in X$, we have $xEy \rightarrow f(x)Ff(y)$. In this language, a Turing invariant function is a homomorphism from \equiv_T to \equiv_T . f is said to be a *cohomomorphism* from E to F if for all $x, y \in X$, we have $f(x)Ff(y) \rightarrow xEy$. f is said to be a *reduction* from E to F if f is simultaneously a homomorphism and a cohomomorphism from E to F . A reduction from E to F induces an injection from the quotient X/E to the quotient Y/F . If the reduction f is itself injective, then f is said to be an *embedding* of E into F .

E is said to be *Borel reducible* to F , noted $E \leq_B F$, if there exists a Borel reduction from E to F . The class of countable Borel equivalence relations under \leq_B has a rich structure that has been studied extensively. See for instance the paper of Jackson, Kechris, and Louveau [11].

We will be particularly interested in the phenomenon of universality. A countable Borel equivalence relation E is said to be *universal* if for all countable Borel equivalence relations F , we have $F \leq_B E$. It is known that there exist universal countable Borel equivalence relations [6].

Martin's conjecture and the partial results surrounding it have turned out to have many connections with the field of countable Borel equivalence relations. Indeed, while Martin's conjecture says something very beautiful and fundamental about Turing reducibility and the hierarchy of definability, it is not so surprising that Martin's conjecture has been more applicable in this area, rather than in recursion theory. Martin's conjecture gives a complete classification of all homomorphisms from Turing equivalence to itself, and homomorphisms are a basic object of study in the area of countable Borel equivalence relations.

A countable Borel equivalence relation E is said to be *hyperfinite* if $E = \bigcup_{i \in \omega} E_i$ where $E_0 \subseteq E_1 \subseteq \dots$ is an increasing sequence of Borel equivalence relations with finite classes. Slaman and Steel [25] realized that if \equiv_T was hyperfinite, this would allow one to construct counterexamples to Martin's conjecture. They showed that \equiv_T is not hyperfinite and they proved that a Borel equivalence relation is hyperfinite if and only if it is induced by a Borel \mathbb{Z} action. They obtained these results

independently from the work that was beginning on the field of Borel equivalence relations at the time. Their last result is due independently to Weiss [32].

In [25], Slaman and Steel posed further structurability questions about Turing equivalence. These were answered by Kechris [12] via methods associated with the concept of amenability. Amenability has since played a large role in the study of Borel equivalence relations.

Kechris [13] has asked whether Turing equivalence is a universal countable Borel equivalence relation. An affirmative answer to this question would contradict Martin's conjecture, while Martin's conjecture implies that \equiv_T is not universal. See [7] for a more thorough discussion of this topic. Essentially, if there is a reduction from $\equiv_T \sqcup \equiv_T$ to \equiv_T , then the range of the reduction on one of the copies of \equiv_T must be disjoint from a cone.

A related question is due to Hjorth:

Question 1.9 (Hjorth [1], [11]). *If E and F are countable Borel equivalence relations on the Polish space X , and E is universal and $E \subseteq F$, then must F be universal?*

If this question has an affirmative answer, then \equiv_T is universal; it is easy to find subsets of \equiv_T that are universal. Of course, an affirmative answer to this question would have many more implications.

Let E be a countable Borel equivalence relation on the Polish space X , and μ be a probability measure on X . Given a countable Borel equivalence relation F , we say that E is *F-ergodic* with respect to μ if every Borel homomorphism from E to F maps a set of measure 1 into a single F -class. E is said to be simply *ergodic* with respect to μ if it is $\Delta(Y)$ -ergodic with respect to μ for every Polish space Y , where $\Delta(Y)$ is the equivalence relation of equality on Y . Define a subset A of X to be *E-invariant* if for all $x, y \in X$, if $x \in A$, and xEy , then $y \in A$. Equivalently, E is ergodic with respect to μ if and only if every Borel E -invariant set has measure 0 or 1.

For the above definitions of ergodicity to make sense, μ can be a measure on merely the σ -algebra of E -invariant Borel subsets of X , as Martin measure is for \equiv_T . For example, \equiv_T is ergodic with respect to Martin measure.

Strong ergodicity results for \equiv_T and Martin measure would be very interesting. Let E_0 be the equivalence relation of equality mod finite on 2^ω . Thomas [30] has shown that if \equiv_T is E_0 -ergodic with respect to Martin measure, then \equiv_T is not Borel bounded. Borel boundedness is closely connected to the long open increasing union problem for hyperfinite equivalence relations [3]. It is currently open whether there are any Borel equivalence relations that are not Borel bounded.

Thomas has shown that Martin's conjecture implies that \equiv_T is E_0 -ergodic with respect to Martin measure, and in fact, Martin's conjecture implies the strongest ergodicity for \equiv_T that is possible with respect to Martin measure. If E and F are countable Borel equivalence relations, then a *weak Borel reduction* is a countable-to-one Borel homomorphism from E to F . If there exists a weak Borel reduction from E to F , then we say that E is *weakly Borel reducible* to F , and write $E \leq_B^w F$. A countable Borel equivalence relation E is said to be *weakly universal* if $F \leq_B^w E$ for all countable Borel equivalence relations F . Clearly, if E is weakly universal, then \equiv_T is not E -ergodic with respect to Martin measure, since there is a countable-to-one Borel homomorphism from \equiv_T to E . Assuming Martin's conjecture, Thomas has proved the remarkable fact that the converse is true:

Theorem 1.10 (Thomas [30]). *Assume Martin's conjecture is true. Let E be any countable Borel equivalence relation. Then exactly one of the following hold:*

- (1) *E is weakly universal.*
- (2) *\equiv_T is E -ergodic, with respect to Martin measure.*

The proof of this theorem uses the fact that Martin's conjecture implies that the saturation of the range of a countable-to-one Turing invariant function must contain a Turing cone. We will discuss Theorem 1.10 more in Section 3.

Martin's conjecture appears to be closely connected to the structure of the weakly universal countable Borel equivalence relations. Thomas [30] has shown that assuming Martin's conjecture, there are continuum many pairwise \leq_B -incomparable weakly universal countable Borel equivalence relations. These equivalence relations are products of the form $\equiv_T \times E_\alpha$ where $\{E_\alpha : \alpha \in 2^\omega\}$ is a family of non weakly universal countable Borel equivalence relations on 2^ω so that if $\alpha \neq \beta$, then E_α is E_β -ergodic with respect to Lebesgue measure. The proof of this result uses Popa's cocycle superrigidity theorem to establish the existence of such a family of E_α , and then applies Theorem 1.10 to prove the \leq_B -incomparability of the product equivalence relations.

Thomas has also used Martin's conjecture to investigate weak universality in another context. Say that a countable group G is *weakly action universal* if there is a Borel action of G on a Polish space X so that the induced orbit equivalence relation E_G^X is weakly universal. Assuming Martin's conjecture, Thomas has shown that G is weakly action universal if and only if the conjugacy relation on the subgroups of G is weakly universal [27].

Aside from these results, the structure of the weakly universal countable Borel equivalence relations is poorly understood. For example, it is open whether there exists more than one weakly universal countable Borel equivalence relation up to Borel reducibility; this is equivalent to Hjorth's Question 1.9 having a negative answer.

An appeal of Martin's conjecture is that it provides a dimension of analysis that is completely orthogonal to measure theory. This is particularly interesting because all other known techniques for analyzing non-hyperfinite countable Borel equivalence relations are measure-theoretic. Assuming Martin's conjecture, Thomas [30] has proved that the complexity of a weakly universal countable Borel equivalence relation always concentrates on a nullset. This is strong evidence that techniques that are not purely measure-theoretic are needed to unravel the structure of the weakly universal countable Borel equivalence relations.

Theorem 1.11 (Thomas [30]). *Assume Martin's conjecture. If E is any weakly universal countable Borel equivalence relation on X , and μ is a Borel probability measure on X , then there is a Borel set $B \subseteq X$ with $\mu(B) = 1$ so that $E \restriction B$ is not weakly universal.*

Thomas has applied this theorem to show that assuming Martin's conjecture, there does not exist a strongly universal countable Borel equivalence relation. We will discuss this result more in Section 3.

The partial results on Martin's conjecture have also found applications in the field of countable Borel equivalence relations. Thomas [29] has used Theorem 1.7 to show the nonexistence of continuous Borel reductions between several equivalence relations. These results are significant because in practice, most Borel reductions

are continuous. Montalbán, Reimann, and Slaman (unpublished) have used Theorem 1.2 to show that \equiv_T is not a uniformly universal countable Borel equivalence relations. We will discuss their theorem more in Section 3.

2. THE UNIVERSALITY OF ARITHMETIC EQUIVALENCE

It is natural to consider analogues of Martin's conjecture for other notions of degree. In particular, this makes sense for any degree notion that has a natural jump operator, and an analogue of Martin's measure (which generally exists by a proof similar to Martin's proof in [19]). For instance, we can replace Turing reducibility by arithmetic reducibility, the Turing jump with $x \mapsto x^{(\omega)}$, and Martin measure with the arithmetic cone measure.

In [25], Slaman and Steel note that their arguments for proving Theorems 1.2 and 1.3 adapt to the Δ_n^1 degrees, and to the degrees of constructibility. However, they also note that their proofs do not work for arithmetic equivalence.

In later work, Slaman and Steel further investigated the analogue of Martin's conjecture for arithmetic equivalence. They showed that it is false, and the technique that they developed to build counterexamples adapted to prove a stronger result: that arithmetic equivalence is a universal countable Borel equivalence relation. It is this long unpublished result that we will give a proof of in this section. In Section 3, we will use this result to prove some theorems about universal countable Borel equivalence relations in general.

2.1. Basic definitions. The Cantor space, noted 2^ω , is the set of all functions from ω to 2. There is a bijection between subsets of ω and elements of 2^ω ; a subset of ω is represented by its characteristic function. In what follows, we freely move between these two representations. Say that $x \in 2^\omega$ has a limit if there exists an i such that $\forall j > i, x(j) = x(i)$. Viewing x as a subset of ω , this is the same as saying that x is finite or cofinite.

Given two reals $x, y \in 2^\omega$, the *join* of x and y is the real $x \oplus y$ defined by $(x \oplus y)(2n) = x(n)$ and $(x \oplus y)(2n+1) = y(n)$ for all $n \in \omega$. The join of finitely many reals is defined analogously. Fix a recursive bijection $\langle \cdot, \cdot \rangle$ from $\omega \times \omega \rightarrow \omega$. Let x be a subset of ω . The *n th column of x* , noted $x^{[n]}$, is the subset of ω defined by $x^{[n]} = \{m : \langle n, m \rangle \in x\}$. Conversely, if $\{x_i\}_{i \in \omega}$ are all reals, then the *join* of these reals, noted $\bigoplus_{i \in \omega} x_i$, is the real whose n th column is x_n .

Let $2^{<\omega}$ be the set of finite binary sequences. If $\sigma \in 2^{<\omega}$, then the length of σ , noted $|\sigma|$, is the domain of σ . If x and y are functions from ω to $2^{<\omega}$, define the join of x and y similarly to the above.

If $x, y \in 2^\omega$, then x is said to be *arithmetically reducible* to y , noted $x \leq_A y$, if there is an n so that x has a Σ_n^0 definition relative to y . Equivalently, $y \geq_A x$ if there is an n so that $y^{(n)} \geq_T x$, where $y^{(n)}$ is the n th iterate of the Turing jump relative to y . The associated countable Borel equivalence relation is called arithmetic equivalence and is noted \equiv_A .

2.2. The proof. Let F_2 be the free group on two generators. We define the countable Borel equivalence relation $E(F_2, 2)$ on 2^{F_2} in the following way: for all $x, y \in 2^{F_2}$, let $x E(F_2, 2) y$ if and only if there exists a $g \in F_2$ so that $x(h) = y(gh)$ for all $h \in F_2$. By a theorem of Dougherty, Jackson, and Kechris [6], this is a universal countable Borel equivalence relation. In order to show that arithmetic equivalence is universal, we shall construct a Borel embedding $f : 2^{F_2} \rightarrow 2^\omega$ of

$E(F_2, 2)$ into \equiv_A . The particular properties of $E(F_2, 2)$ will be unimportant to the proof which would work equally well with any equivalence relation generated by the Borel action of a finitely generated group.

When constructing f , we must satisfy two conflicting requirements: we must make f both a homomorphism and a cohomomorphism. In making f a homomorphism, we must ensure that if $xE(F_2, 2)y$, then $f(x) \equiv_A f(y)$. Let $\{w_i\}_{i \in \omega}$ be a recursive listing of all the words in F_2 . We will ensure that f is a homomorphism by fixing a way of “coding” $f(w_i \cdot x)$ into $f(x)$, for every i .

An obvious method of coding would be as follows. Let $g : 2^{F_2} \rightarrow 2^\omega$ be any Borel function. Then define $\tilde{g} : 2^{F_2} \rightarrow 2^\omega$ to be

$$\tilde{g}(x) = \bigoplus_{i \in \omega} g(w_i \cdot x).$$

Given any g , we see that \tilde{g} is a homomorphism from $E(F_2, 2)$ to \equiv_A ; from $\tilde{g}(x)$, we can obtain any $\tilde{g}(w_i \cdot x)$ by recursively permuting columns. The task, then, would be to construct a Borel g so that the associated \tilde{g} was also a cohomomorphism.

Unfortunately, this approach is doomed to failure. If such a \tilde{g} was a Borel reduction of $E(F_2, 2)$ to \equiv_A , it would also be a Borel reduction of $E(F_2, 2)$ to \equiv_T , and it would be a uniform reduction. Montalbán, Reimann, and Slaman have shown this is impossible. We will discuss their result more in Section 3.

Essentially, the problem is that the above coding is too easy to unravel compared to how powerful arithmetic reductions are (or even how powerful Turing reductions are). The coding we use must evidently match the power of arithmetic equivalence more closely.

Our failed attempt above is interesting in the context of Hjorth’s Question 1.9. Suppose E and F are countable Borel equivalence relations, and $E \subseteq F$. A plausible intuition as to why the universality of E would imply the universality of F is as follows: it might be that any coding mechanism we could use to prove E universal must also work to prove F universal, simply by taking a more “generic” function that uses this coding. However, the above example shows that this is false; there are equivalence relations that are subsets of \equiv_A for which the above coding mechanism can be used to prove universality.

The crux of the proof that \equiv_A is universal is a method of coding so that for every n , there are only finitely many words w_i so that $f(w_i \cdot x)$ is Σ_n definable from $f(x)$. Hence, from the perspective of a Σ_n reduction, $f(x)$ behaves as essentially a finite join. By taking a generic function f for this type of coding, we can control these finite joins, and ensure that our f is a cohomomorphism.

Definition 2.1. Given $y, z \in 2^\omega$, say that z *jump codes* y if for every n , $z^{[n]}$ has a limit, and $y(n) = \lim_m z^{[n]}(m)$. The *Skolem function* for this jump coding is the function from ω to ω that maps n to the least i such that $\forall j \geq i [z(\langle n, j \rangle) = z(\langle n, i \rangle)]$.

The name of this coding derives from the fact that if z jump codes y , then $z' \geq_T y$. Indeed, using z' as an oracle, we can compute both y and the Skolem function for this jump coding. Given n , find the least i so that $\forall j > i [z(\langle n, j \rangle) = z(\langle n, i \rangle)]$, using the oracle z' . Then the n th bit of y is $z(\langle n, i \rangle)$.

Definition 2.2. Let $x : \omega \rightarrow 2^{<\omega}$ be any function. For any real $y \in 2^\omega$, define $J(x, y) \in 2^\omega$ to be the real that jump codes y via x . Precisely, we mean that the

n th column of $J(x, y)$ will be

$$(J(x, y))^{[n]} = \begin{cases} x(n)10000\dots & \text{if } y(n) = 0 \\ x(n)01111\dots & \text{if } y(n) = 1 \end{cases}$$

Hence, $J(x, y)$ jump codes y , and the Skolem function for the jump coding is $n \mapsto |x(n)| + 1$, where $|x(n)|$ is the length of the finite sequence $x(n)$.

If p is a partial function from ω to $2^{<\omega}$ and r is a partial function from ω to 2 with $\text{dom}(p) \subseteq \text{dom}(r)$, analogously define $J(p, r)$, a partial function from ω to 2, where the n th column of $J(p, r)$ is undefined if $n \notin \text{dom}(p)$.

The idea of coding a real as a limit of columns has a long history in recursion theory. The proof we will present uses jump codings of “depth” ω . In this way, it is reminiscent of some constructions that have been used to investigate the structure $\langle \mathbf{D}, \leq_T, \cdot \rangle$ of the Turing degrees under \leq_T and the jump operator. See the papers of Hinman and Slaman [10], and Montalbán [20].

In what follows, we will be using ideas from forcing in arithmetic, and in particular, reals with limited Cohen genericity. Let $\mathbb{P}_{\omega, 2^{<\omega}}$ be the partial order of finite partial functions from ω to $2^{<\omega}$ ordered under inclusion. Say that a function x from ω to $2^{<\omega}$ is *arithmetically generic* if it meets every arithmetically definable dense subset of $\mathbb{P}_{\omega, 2^{<\omega}}$. Similarly, finitely many functions x_1, \dots, x_n from ω to $2^{<\omega}$ are *mutually arithmetically generic* if (x_1, \dots, x_n) meets every arithmetically definable dense subset of $(\mathbb{P}_{\omega, 2^{<\omega}})^n$.

We begin with a lemma whose proof is standard for the subject:

Lemma 2.3. *If x, z , and w are mutually arithmetically generic functions from ω to $2^{<\omega}$, then for all $n \in \omega$ and $y \in 2^\omega$,*

- (1) $(0^{(n)} \oplus J(x, y) \oplus z)' \equiv_T 0^{(n+1)} \oplus x \oplus y \oplus z$
- (2) $0^{(n)} \oplus J(x, y) \oplus z \not\leq_T w$

Proof. We prove part 1. Let $\mathbb{P}_{\omega, 2}$ be the partial order of finite partial functions from ω to 2 ordered under inclusion.

Fix an e . Consider the set D of pairs $(p, q) \in (\mathbb{P}_{\omega, 2^{<\omega}})^2$ such that for every $r \in \mathbb{P}_{\omega, 2}$ with $\text{dom}(p) = \text{dom}(r)$, either $\varphi_e(0^{(n)} \oplus J(p, r) \oplus q)$ halts, or for every extension of (p, q, r) to (p^*, q^*, r^*) , we have that $\varphi_e(0^{(n)} \oplus J(p^*, r^*) \oplus q^*)$ does not halt. We claim that D is dense in $(\mathbb{P}_{\omega, 2^{<\omega}})^2$.

Suppose $(p, q) \in (\mathbb{P}_{\omega, 2^{<\omega}})^2$. We wish to show that (p, q) can be extended to meet D . Let r_1, \dots, r_n be a list of all elements of $\mathbb{P}_{\omega, 2}$ such that $\text{dom}(p) = \text{dom}(r_i)$. Let $s_0 = \emptyset$, and $q_0 = q$. We will define an increasing sequence $s_1 \subseteq \dots \subseteq s_n$ of elements of $\mathbb{P}_{\omega, 2}$ and an increasing sequence $q_1 \subseteq \dots \subseteq q_n$ of elements of $\mathbb{P}_{\omega, 2^{<\omega}}$.

Inductively, for $1 \leq i \leq n$, consider $0^{(n)} \oplus J(p, r_i) \sqcup s_{i-1} \oplus q_{i-1}$, a partial function from ω to 2. Either there no extension of this partial function that makes φ_e halt relative to it, or there is a finite such extension. If there is such an extension, let it be $0^{(n)} \oplus J(p, r_i) \sqcup s_i \oplus q_i$, where q_i extends q_{i-1} , where s_i extends s_{i-1} , and the domain of s_i is disjoint from $J(p, r_i)$. If there is no such extension, let $q_i = q_{i-1}$, and $s_i = s_{i-1}$.

Extend p to any \hat{p} so that for every $\langle j, k \rangle \in \text{dom}(s_n)$, we have $\hat{p}(j)(k) = s_n(\langle j, k \rangle)$. Note that this means that for any $r \in \mathbb{P}_{\omega, 2}$ with $\text{dom}(r) = \text{dom}(\hat{p})$, $J(\hat{p}, r)$ will be an extension of $J(p, r) \sqcup s_n$. It is clear that (\hat{p}, q_n) meets D .

If x and z are arithmetically generic, then for each e , $0^{(n+1)} \oplus x \oplus y \oplus z$ can compute a place where (x, z) meets D . Hence, from $0^{(n+1)} \oplus x \oplus y \oplus z$ we can compute the

Σ_1^0 theory of $0^{(n)} \oplus J(x, y) \oplus z$, and thus $0^{(n+1)} \oplus x \oplus y \oplus z \geq_T (0^{(n)} \oplus J(x, y) \oplus z)'$. Obviously $(0^{(n)} \oplus J(x, y) \oplus z)' \geq_T 0^{(n+1)} \oplus x \oplus y \oplus z$.

We now proceed to part 2, whose proof is similar to part 1. Fix an e . The dense set that (x, z, w) must meet is the set of triples $(p, q, r) \in (\mathbb{P}_{\omega, 2^{<\omega}})^3$ such that for every $s \in \mathbb{P}_{\omega, 2}$ with $\text{dom}(p) = \text{dom}(s)$, there exists a k such that $\varphi_e(0^{(n)} \oplus J(p, s) \oplus q)(k) \downarrow \neq r(k)$, or for every extension of (p, q, s) to (p^*, q^*, s^*) , we have that $\varphi_e(0^{(n)} \oplus J(p, s) \oplus q)(k)$ does not halt. We leave the rest of the proof to the reader. \square

Note that for all x_0, \dots, x_n and y_0, \dots, y_n , we have that

$$J(x_0, y_0) \oplus \dots \oplus J(x_n, y_n) \equiv_T J(x_0 \oplus \dots \oplus x_n, y_0 \oplus \dots \oplus y_n)$$

and that if x_0, \dots, x_n and z_0, \dots, z_n are all mutually arithmetically generic, then $x_0 \oplus \dots \oplus x_n$ and $z_0 \oplus \dots \oplus z_n$ are mutually arithmetically generic. Therefore, we can conclude a more general fact:

Lemma 2.4. *If $x_0, \dots, x_i, z_0, \dots, z_j$, and w are mutually arithmetically generic functions from ω to $2^{<\omega}$, then for all $n \in \omega$ and $y_0, \dots, y_i \in 2^\omega$*

$$\begin{aligned} (1) \quad & \left(0^{(n)} \oplus J(x_0, y_0) \oplus \dots \oplus J(x_i, y_i) \oplus z_0 \oplus \dots \oplus z_j \right)' \\ & \equiv_T 0^{(n+1)} \oplus x_0 \oplus \dots \oplus x_i \oplus y_0 \oplus \dots \oplus y_i \oplus z_0 \oplus \dots \oplus z_j. \\ (2) \quad & 0^{(n)} \oplus J(x_0, y_0) \oplus \dots \oplus J(x_i, y_i) \oplus z_0 \oplus \dots \oplus z_j \not\geq_T w \end{aligned}$$

We are ready to prove the universality of arithmetic equivalence.

Theorem 2.5 (Slaman and Steel). \equiv_A is a universal countable Borel equivalence relation.

Proof. Let $F_2 = \langle a, b \rangle$. To prove this theorem, we will construct a Borel embedding of $E(F_2, 2)$ into \equiv_A . Let $g : 2^{F_2} \rightarrow (2^{<\omega})^\omega$ be a Borel function so that for every distinct $x_0, \dots, x_n \in 2^{F_2}$, we have that $g(x_0), \dots, g(x_n)$ are all mutually arithmetically generic functions from ω to $2^{<\omega}$. The definition of the embedding $f : 2^{F_2} \rightarrow 2^\omega$ is as follows:

$$f(x) = J(g(x), f(a \cdot x) \oplus f(a^{-1} \cdot x) \oplus f(b \cdot x) \oplus f(b^{-1} \cdot x)).$$

Note that while our definition of f is self-referential, it is not circular, as one can see by repeatedly expanding the terms involving f on the right hand side, using the definition of f .

First, f is a homomorphism. Recall that for all x and y , $J(x, y)' \geq_T y$. Hence, if $x = w \cdot y$ where w is a word of F_2 of length n , then $(f(x))^{(n)} \geq_T f(y)$.

Thus, we simply need to show that f is a cohomomorphism. That is, if x and y are not $E(F_2, 2)$ equivalent, then $f(x)$ and $f(y)$ are not arithmetically equivalent. Let $\{w_i : |w_i| < n\}$ be all words in F_2 of length $< n$, and let $\{w_i : |w_i| = n\}$ be all words in F_2 of length n . Then

$$(f(x))^{(n)} \equiv_T 0^{(n)} \oplus \bigoplus_{\{w_i : |w_i| < n\}} g(w_i \cdot x) \oplus \bigoplus_{\{w_i : |w_i| = n\}} f(w_i \cdot x)$$

as one can see by inductively using part 1 of Lemma 2.4. (Recall that by definition, $f(z)$ is of the form $J(g(z), w)$ for some w , and $g(z)$ is part of our set of mutual generics). Hence, if x and y are not $E(F_2, 2)$ equivalent, by part 2 of Lemma 2.4, we see $(f(x))^{(n)} \not\geq_T g(y)$ for all n . Hence, $(f(x))^{(n-1)} \not\geq_T f(y)$, since $f(y)' \geq_T g(y)$. \square

The original proof of the existence of pathological arithmetically invariant functions was a similar construction to produce an embedding of \equiv_A into itself. Note that the range of the embedding in Theorem 2.5 is disjoint from the arithmetic cone $\{x : x \geq_A 0^\omega\}$. Hence, embedding \equiv_A into itself via this technique produces an injective arithmetically invariant function whose range is disjoint from an arithmetic cone.

3. COROLLARIES AND OPEN PROBLEMS

A measure analogous to Martin measure exists for arithmetic equivalence. It is called the *arithmetic cone measure*. An arithmetic cone is a set of the form $\{x : x \geq_A y\}$ for some y . An arithmetically invariant set has measure 1 with respect to the arithmetic cone measure if it contains an arithmetic cone, otherwise it has measure 0. Martin's proof in [19] still works when Turing reducibility is replaced by arithmetic reducibility. Hence, this function is indeed a measure on the σ -algebra of arithmetically invariant sets.

The proof that arithmetic equivalence is universal relativizes. That is, for every x , arithmetic equivalence relative to x is universal. Equivalently, arithmetic equivalence restricted to any arithmetic cone is universal. Using this fact, we can obtain several interesting corollaries about universal countable Borel equivalence relations in general. The results in this section are due to the first author.

Jackson, Kechris, and Louveau [11] have asked the following question: suppose E is a universal countable Borel equivalence relation on X , and B is an E -invariant Borel subset of X . Is one of $E \upharpoonright B$ or $E \upharpoonright (X \setminus B)$ universal? The answer is yes, and we prove a stronger fact, originally posed as a question by Thomas [31, question 3.20].

Theorem 3.1. *Suppose X and Y are Polish spaces, E is a universal countable Borel equivalence relation on X , and $f : X \rightarrow Y$ is any Borel homomorphism from E to $\Delta(Y)$, where $\Delta(Y)$ is the relation of equality on Y . Then there exists a $y \in Y$ so that the restriction of E to $f^{-1}(y)$ is a universal countable Borel equivalence relation.*

Proof. First, note that it is enough to prove this for arithmetic equivalence. Let E and f be as in the statement of the theorem, and let $g : 2^\omega \rightarrow X$ be a Borel reduction from \equiv_A to E . If arithmetic equivalence restricted to $(f \circ g)^{-1}(y)$ is universal, then E restricted to $f^{-1}(y)$ is universal.

Now let f be a homomorphism from \equiv_A to $\Delta(Y)$. Since arithmetic equivalence is ergodic with respect to the arithmetic cone measure, there must be a $y \in Y$ so that $f^{-1}(y)$ contains an arithmetic cone. Arithmetic equivalence restricted to this set is thus universal. \square

The use of Borel determinacy in our proof raises an interesting metamathematical question: must any proof of this theorem use Borel determinacy? For instance, one could ask whether Theorem 3.1 implies Borel determinacy over some simple base theory. We ask a weaker question of whether Theorem 3.1 shares a metamathematical property of Borel determinacy:

Question 3.2. *Does a proof of Theorem 3.1 require the existence of ω_1 iterates of the powerset of ω ?*

Let E be a countable Borel equivalence relation, and suppose f is a Borel homomorphism from \equiv_A to E . Then f is also a Borel homomorphism from \equiv_T to E . If $B \subseteq 2^\omega$ contains a Turing cone, then the \equiv_A -saturation of B must contain an arithmetic cone. It is therefore possible to use ergodicity results about Turing equivalence and Martin measure to obtain ergodicity results about arithmetic equivalence and the arithmetic cone measure. We will apply Thomas' Theorem 1.10 in this way to prove an analogous sort of ergodicity result for all universal countable Borel equivalence relations.

Theorem 3.3. *Assume Martin's conjecture is true. Suppose E is a universal countable Borel equivalence relation, and F is an arbitrary countable Borel equivalence relation. Then exactly one of the following holds:*

- (1) F is weakly universal.
- (2) For every Borel homomorphism f of E into F , there is a single F -class whose preimage B has the property that $E \restriction B$ is universal.

Proof. As in the proof of Theorem 3.1, we only need to prove this when E is \equiv_A . Let f be a homomorphism from \equiv_A to F . Then f is also a homomorphism from \equiv_T to F , and hence by Theorem 1.10, either F is weakly universal, or there is a single F -class whose preimage B contains a Turing cone. In this latter case, since f is also a homomorphism from \equiv_A to F , the preimage of this single F -class contains the \equiv_A -saturation of this Turing cone which is an arithmetic cone. Hence, since B contains an arithmetic cone, $\equiv_A \restriction B$ is universal. \square

In [30], Thomas proved a variant of this theorem where the assumption that E is universal is changed to say E is weakly universal, and option 2 is changed to say that $E \restriction B$ is weakly universal. Theorem 3.3 strengthens this fact; by a result of Miller and Kechris [31], E is a weakly universal countable Borel equivalence relation if and only if there exists an $F \subseteq E$ that is a universal countable Borel equivalence relation.

In the proof of Theorem 3.3, we have used the ergodicity of \equiv_T that follows from Martin's conjecture. However, we only need the weaker ergodicity which Martin's conjecture implies for arithmetic equivalence. We isolate this in the following conjecture. It may be that it is easier to prove ergodicity results for arithmetic equivalence and the arithmetic cone measure than it is for Turing equivalence and Martin measure.

Conjecture 3.4. *Let E be any countable Borel equivalence relation. Then exactly one of the following holds:*

- (1) E is weakly universal.
- (2) \equiv_A is E -ergodic, with respect to the arithmetic cone measure.

A special case of the above conjecture is quite interesting. Thomas [30] has raised the question of whether \equiv_T is E_0 -ergodic with respect to Martin measure. It is weaker to ask whether arithmetic equivalence is E_0 -ergodic with respect to the arithmetic cone measure, but this would have similarly nice consequences. For example, it would imply that \equiv_A is not Borel bounded, and also that option 2 in Theorem 3.3 holds when F is E_0 without the assumption of Martin's conjecture.

For our next application, we will need to recall some facts about pointed perfect sets. Recall that a perfect subset of a Polish space X is a closed subset of X with no isolated points. Every perfect subset of 2^ω can be realized as the paths $[T]$ through

some infinite perfect tree T in $2^{<\omega}$. A *pointed perfect tree* T is a tree T so that for all $x \in [T]$, $x \geq_T T$. A *pointed perfect set* is the paths $[T]$ through some pointed perfect tree T . Pointed perfect sets arise naturally in determinacy arguments, and have many nice properties.

Given a perfect subset $[T]$ of 2^ω , it is clear that 2^ω is homeomorphic to $[T]$ via a canonical homeomorphism that preserves the ordering on 2^ω . This homeomorphism will preserve the Turing degrees above T if T is pointed. That is, let $f : 2^\omega \rightarrow [T]$ be this canonical homeomorphism. If T is a pointed perfect tree, then for all $x \geq_T T$, we have $x \equiv_T f(x)$, since both x and $f(x)$ can compute a representation of T and hence also a representation of f . The analogous facts also hold for arithmetic equivalence. In particular, if T is a pointed perfect tree, and $f : 2^\omega \rightarrow [T]$ is the canonical homeomorphism from 2^ω to $[T]$, then for all $x \geq_A T$, we will have $x \equiv_A f(x)$. Hence, the restriction of \equiv_A to any pointed perfect set is still a universal countable Borel equivalence relation.

We will use the following lemma, which illustrates a useful feature of pointed perfect sets in determinacy arguments. The proof of this lemma is a slight variation of Martin's cone theorem in [19].

Lemma 3.5 (Martin [19]). *Assume $\text{ZF} + \text{DC} + \text{AD}$. Then given any function $\pi : 2^\omega \rightarrow \omega$, there exists a pointed perfect set on which π is constant.*

Proof. Consider the game where I plays $e \in \omega$ followed by $x \in 2^\omega$, and II plays $y \in 2^\omega$, where the players alternate playing bits of these reals as usual. Let II lose unless $y \geq_T x$, and if the game is not decided by this condition, then I wins if and only if $x \geq_T y$, and $\pi(x) = e$.

Given any strategy τ for II, I can win by playing $\pi(\tau)$ followed by τ . Hence, I wins this game. Let σ be a winning strategy for I. Then our pointed perfect set is the set of I's winning plays against II playing $\{y : y \geq_T \sigma\}$. \square

If E and F are countable Borel equivalence relations, then we say that E is *Borel embeddable* in F and write $E \sqsubseteq_B F$ if there exists a Borel embedding of E into F . We can use the above lemma to derive the following fact about universality for embeddings.

Theorem 3.6. *Let E be a universal countable Borel equivalence relation. Then given any countable Borel equivalence relation F , it must be that $F \sqsubseteq_B E$. That is, not only is $F \leq_B E$ (since E is universal), we can always find an injective Borel reduction.*

Proof. First recall that the reduction from $E(F_2, 2)$ to \equiv_A in the proof of Theorem 2.5 is actually a Borel embedding, and not merely a Borel reduction. Of course, this remains true when the proof is relativized to any pointed perfect set. Recall also that Dougherty, Jackson, and Kechris [6] have shown that every countable Borel equivalence relation embeds into $E(F_2, 2)$. Hence, it will be enough to show that there is an embedding of \equiv_A restricted to some pointed perfect set into E .

Since E is countable universal, there is a Borel reduction f from \equiv_A to E . Using Lusin-Novikov uniformization (18.10, 18.15 in [14]), split 2^ω into countably many Borel pieces $\{B_i\}_{i \in \omega}$ so that f is injective on each B_i . One of these B_i must contain a pointed perfect set by Lemma 3.5. \square

This theorem is an interesting counterpoint to the following theorem of Thomas:

Theorem 3.7 (Thomas [28]). *There exist countable Borel equivalence relations E and F such that the equivalence classes of both E and F are all infinite, and $E \leq_B F$, and $F \leq_B E$, but it is not the case that $E \sqsubseteq_B F$.*

Lemma 3.5 also gives an easy proof of the following:

Theorem 3.8. *Suppose E is a universal countable Borel equivalence relation on a Polish space X , and let $\{B_i\}_{i \in \omega}$ be a partition of X into countably many (not necessarily E -invariant) Borel pieces. Then there exists some i such that $E \upharpoonright B_i$ is a universal countable Borel equivalence relation.*

Proof. As in Theorem 3.1, we only need to prove this for \equiv_A . Let $\{B_i\}_{i \in \omega}$ be a partition of 2^ω into countably many Borel pieces. By Lemma 3.5 above, one of these pieces must contain a pointed perfect set, and the restriction of \equiv_A to any pointed perfect set is countable universal. \square

If the B_i in the above theorem are all E -invariant, this theorem follows from Theorem 3.1. From this, we could also conclude the general case since for any Borel B , $E \upharpoonright B$ is universal if and only if $E \upharpoonright [B]_E$ is universal, where $[B]_E$ is the E -saturation of B .

Theorem 3.8 associates two natural σ -ideals to every countable Borel equivalence relation.

Definition 3.9. Let E be a countable Borel equivalence relation on the Polish space X . Define the *non-universal ideal* of E to be the Borel subsets B of X on which $E \upharpoonright B$ is not universal. Define the *non-weakly-universal ideal* of E to be the Borel subsets B of X on which $E \upharpoonright B$ is not weakly universal.

We will discuss these σ -ideals more in what follows. They seem to be important for developing the theory of universal and weakly universal countable Borel equivalence relations.

Let E be a countable Borel equivalence relation on the Polish space X which is equipped with an invariant ergodic Borel probability measure μ . Say that E is *strongly universal* if $E \upharpoonright B$ is universal for every Borel $B \subseteq X$ with $\mu(B) = 1$. In [31], Thomas asked whether there exists a strongly universal countable Borel equivalence relation. Thomas later settled this question under the assumption of Martin's conjecture using Theorem 1.11. We are able to prove a weaker theorem without the assumption of Martin's conjecture.

Theorem 3.10. *Let E be a universal countable Borel equivalence relation on the space X , and let μ be a Borel probability measure on X . Then there is a measure 0 subset B of X for which $E \upharpoonright B$ is a universal countable Borel equivalence relation.*

First, recall the following theorem of Sacks (we give the relativized version of the theorem):

Theorem 3.11 (Sacks [21]). *If μ is a Borel probability measure on 2^ω , then for all $x \in 2^\omega$ such that there exists a representation $y \in 2^\omega$ of μ such that $x >_T y$, the cone $\{z : z \geq_T x\}$ has μ -measure 0.*

Hence, for any Borel probability measure, sufficiently complicated cones are always nullsets. The same theorem is also true when Turing reducibility is replaced with arithmetic reducibility. One way to see this is to first replace our measure μ with an \equiv_A -quasi-invariant measure ν that dominates μ . Then we can find a Turing

cone with ν measure 0, and the \equiv_A -saturation of this cone will be the arithmetic cone with the same base.

Sacks' theorem implies that Martin measure and likewise the arithmetic cone measure cannot be extended to probability measures on all the Borel sets of 2^ω . Pointed perfect sets seem to be as close as we can get to being able to measure arbitrary Borel sets using these measures.

Proof of Theorem 3.10: Again, we need only prove this for arithmetic equivalence; given any other universal countable Borel equivalence relation E on the space X with Borel probability measure μ , by Theorem 3.6 let f be a Borel embedding from \equiv_A to E . Presuming the range of f has positive μ -measure, let ν be the measure on 2^ω defined by $\nu(A) = \frac{1}{\mu(f(2^\omega))} \mu(f(A))$. If $\equiv_A \upharpoonright B$ is universal and $\nu(B) = 0$, then $E \upharpoonright f(B)$ is also universal, and $\mu(f(B)) = 0$.

As we have shown above, given any Borel probability measure μ on \equiv_A , there is an arithmetic cone with measure 0, and \equiv_A restricted to this cone is universal. \square

The extra leverage that Thomas gets by assuming Martin's conjecture is that for all Borel B , $\equiv_T \upharpoonright B$ is weakly universal if and only if B contains a pointed perfect set. Hence if B is \equiv_T -invariant, then $\equiv_T \upharpoonright B$ is weakly universal if and only if $\equiv_T \upharpoonright (2^\omega \setminus B)$ is not weakly universal.

This exact classification of the non-weakly-universal ideal for \equiv_T that follows from Martin's conjecture seems very useful.

Question 3.12. *Are there “nice” characterizations of the non-weakly-universal ideals of naturally occurring weakly universal countable Borel equivalence relations?*

One could also ask the same question for universal countable Borel equivalence relations, and the non-universal ideal. Theorem 3.10 seems to rule out characterizations that are based purely on measure theory. The fact that these ideals do not seem to be measure-theoretic is very interesting, since all known theorems in the field of countable Borel equivalence relations that distinguish between non-hyperfinite countable Borel equivalence relations are based on measure theory.

Marks [18] raises a question that seems to be relevant. Define a countable Borel equivalence relation E to be *measure universal* if for every countable Borel equivalence relation F on a Polish space X equipped with a Borel probability measure μ , there exists a $B \subseteq X$ that is F -invariant, and $\mu(B) = 1$, so that $F \upharpoonright B$ is Borel reducible to E .

Question 3.13 (Marks [18]). *If F is a countable Borel equivalence relation that is measure universal, is F universal?*

This question was motivated by a result in Marks [18] that many-one equivalence and recursive isomorphism are measure universal. It remains open whether these equivalence relations are universal.

3.1. Some questions on uniformity. Borel Martin's conjecture reduces purely to a question about uniformity, as shown in Theorem 1.8. If we embrace Martin's conjecture and ponder what larger principle it might embody, we are naturally led to the possibility that similar principles of uniformity might exist amongst a much wider class of equivalence relations, even though the original form of Martin's conjecture appears to hinge on specific properties of Turing equivalence that do not generalize to many equivalence relations. This is an intriguing possibility that

would lead to a compelling theory providing a systematic way to explain many phenomena. In this section, we shall adopt such a viewpoint and pose several questions about uniformity in broader contexts. Our questions will be phrased so that affirmative answers would be the most natural from the above perspective. However, even negative answers would be very interesting as they might provide starting points for constructing counterexamples to Martin's conjecture.

Admittedly, we currently have little evidence supporting the viewpoint we shall outline. Such questions of uniformity are presently poorly understood, and these issues appear quite deep. We know of no general theorems in this area, and not even any theorems in specific cases, beyond the work in [25]. Likewise, there are few examples of nonuniformity which seem to have much bearing on the questions we will ask.

Consider, for instance, the case of arithmetic equivalence. We have seen above that the analogue of Martin's conjecture fails for arithmetic equivalence. However, many questions about arithmetically invariant functions remain, and chief among them is the arithmetic analogue of Conjecture 1.4. Say that an arithmetically invariant function f is *uniformly arithmetically invariant* if there exists a function $u : \omega^2 \rightarrow \omega^2$ such that if $x \equiv_A y$ via (i, j) , then $f(x) \equiv_A f(y)$ via $u(i, j)$.

Question 3.14 (ZF + DC + AD). *If $f : 2^\omega \rightarrow 2^\omega$ is arithmetically invariant, then is there a uniformly arithmetically invariant g which is defined on an arithmetic cone so that $f(x) \equiv_A g(x)$ on an arithmetic cone?*

Little is known about this question. The pathological arithmetically invariant functions that were constructed in Section 2.2 are all uniformly invariant, and the technique used to construct them gives no hint about questions of nonuniformity. Likewise, the following conjecture is particularly interesting in light of the earlier results in this section:

Conjecture 3.15. *If f is a Borel homomorphism from \equiv_A to \equiv_T , then there exists a Borel homomorphism g from \equiv_A to \equiv_T so that $f(x) \equiv_A g(x)$ on an arithmetic cone and g is uniform in the sense that there exists a function $u : \omega^2 \rightarrow \omega^2$ so that for all x and y , if $x \equiv_A y$ via (i, j) , then $g(x) \equiv_T g(y)$ via $u(i, j)$.*

This conjecture is weaker than Borel Martin's conjecture, but it has many of the same consequences for the theory of Borel equivalence relations. For instance, it implies that Conjecture 3.4 is true, and hence that Theorem 3.3 is true without the assumption of Martin's conjecture. It also implies that Turing equivalence is not a universal countable Borel equivalence relation. This is because it rules out an embedding of \equiv_A into \equiv_T ; for all α with $\omega \leq \alpha < \omega_1$, the map $x \mapsto x^{(\alpha)}$ is not a reduction of arithmetic equivalence restricted to any arithmetic cone into \equiv_T .

It seems interesting to consider questions of uniformity analogous to Conjecture 3.15 for most other equivalence relations from recursion theory. Even more generally, we shall formulate such questions for arbitrary weakly universal countable Borel equivalence relations.

In the field of countable Borel equivalence relations, uniformity is usually discussed in the context where an equivalence relation E is equipped with a group G and a Borel action of G that generates E . If G is a countable group that acts on a Polish space X , define the orbit equivalence relation E_G^X where $x E_G^X y$ if and only if there exists a $g \in G$ such that $g \cdot x = y$. By a result of Feldman and Moore [9], every countable Borel equivalence relation E is of this form.

In recursion theory, however, most equivalence relations (for instance \equiv_T and \equiv_A) are not naturally generated by group actions. Further, while the Feldman-Moore theorem guarantees that it is possible to construct group actions that generate recursion-theoretic equivalence relations, it is often difficult to work with them using tools from recursion theory. Thus, when working with weakly universal equivalence relations, it seems natural to expand our definitions, since recursion-theoretic equivalence relations seem so important in this context.

Definition 3.16. A *generating family of partial Borel functions* on a Polish space X is a countable set $\{\phi_i\}$ of partial Borel functions on X that is indexed by natural numbers (though we will omit the indexing for clarity), contains the identity function, and is closed under composition. Precisely, by partial Borel function on X , we mean that the domain of each ϕ_i is a Borel subset of X , and that the function $\phi_i : \text{dom}(\phi_i) \rightarrow X$ is a Borel function. Such a generating family induces an equivalence relation $E_{\{\phi_i\}}^X$, where $x E_{\{\phi_i\}}^X y$ if and only if there exists ϕ_i and ϕ_j so that $\phi_i(x) = y$, and $\phi_j(y) = x$. In this case, say that $x E_{\{\phi_i\}}^X y$ via (i, j) .

We will use the notation $E_{\{\phi_i\}}^X$ to indicate a countable Borel equivalence relation on the Polish space X that is induced by the generating family of partial Borel functions $\{\phi_i\}$.

For example, the Turing reductions are a generating family of partial Borel functions for \equiv_T , and the arithmetic reductions are a generating family of partial Borel functions for \equiv_A .

Definition 3.17. Suppose $E_{\{\phi_i\}}^X$ and $E_{\{\psi_i\}}^Y$ are countable Borel equivalence relations on the Polish spaces X and Y induced by the generating families of partial Borel functions $\{\phi_i\}$ and $\{\psi_i\}$. Say that a partial homomorphism $f : X \rightarrow Y$ is *uniform (with respect to $\{\phi_i\}$ and $\{\psi_i\})$* if there exists a function $u : \omega^2 \rightarrow \omega^2$ such that for all $x, y \in X$, if $x E_{\{\phi_i\}}^X y$ via (i, j) , then $f(x) E_{\{\psi_i\}}^Y f(y)$ via $u(i, j)$.

Let E_G^X be a countable Borel equivalence relation generated by a Borel action of the countable group G . To each $g \in G$ we associate the Borel automorphism $\phi_g(x) = g \cdot x$ of X , and so E_G^X is the same as the equivalence relation $E_{\{\phi_g\}}^X$ given by the generating family $\{\phi_g\}$. Say that E_G^X is *freely generated* if for all $g \in G$ and for all $x \in X$, if $g \cdot x = x$ then $g = 1$. In the context where E_G^X and E_H^Y are freely generated countable Borel equivalence relations, then in the measure context, the uniformity defined above is equivalent to saying that the cocycle induced by a homomorphism between equivalence relations is cohomologous to a group homomorphism. Thus, the sort of uniformity implied by Martin's conjecture (and more general questions which we will soon discuss) shares something of the same spirit as cocycle superrigidity which was introduced by Zimmer [34]. Cocycle superrigidity has since played an important part in developing the theory of countable Borel equivalence relations.

We will now formulate an analogue of Conjecture 3.15 for homomorphisms between two arbitrary weakly universal countable Borel equivalence relations. In posing such a question, we need an equivalent of a set of Martin measure 1; a “large” subset of the underlying space on which we demand that uniformity is witnessed. Here, the natural candidate is an invariant Borel set such that the restriction of the equivalence relation to this set is still weakly universal. This notion agrees with

Martin measure in the case of \equiv_T . The fact that the non-weakly-universal Borel sets form a σ -ideal is further evidence that this is a good notion of “largeness”.

Note that it is certainly not the case that for every homomorphism f between equivalence relations $E_{\{\phi_i\}}^X$ and $E_{\{\psi_i\}}^Y$, there exists a uniform homomorphism g from $E_{\{\phi_i\}}^X$ to $E_{\{\psi_i\}}^Y$ so that $f(x)E_{\{\psi_i\}}^Y g(x)$ for all x . There are trivial counterexamples exploiting partiality of generating families. Even in the case of equivalence relations freely generated by the actions of countable groups, not every cocycle associated to a homomorphism of such equivalence relations is cohomologous to a group homomorphism.

We proceed to our question:

Question 3.18. *Let $E_{\{\phi_i\}}^X$ and $E_{\{\psi_i\}}^Y$ be weakly universal countable Borel equivalence relations. Now suppose f is a homomorphism from $E_{\{\phi_i\}}^X$ to $E_{\{\psi_i\}}^Y$. Must there be an $E_{\{\phi_i\}}^X$ -invariant subset B of X such that $E_{\{\phi_i\}}^X \upharpoonright B$ is weakly universal, and a uniform partial homomorphism $g : X \upharpoonright B \rightarrow Y$ from $E_{\{\phi_i\}}^X$ to $E_{\{\psi_i\}}^Y$ such that $f(x)E_{\{\psi_i\}}^Y g(x)$ for all $x \in B$?*

As stated, an affirmative answer to this question does not seem to generalize Borel Martin's conjecture. For this to be the case, we also need a characterization of the non-weakly-universal ideal of Turing equivalence.

Definition 3.19. Suppose that $E_{\{\phi_i\}}^X$ is a weakly universal countable Borel equivalence relation. Say that $E_{\{\phi_i\}}^X$ is *uniformly weakly universal* if for every $E_{\{\psi_i\}}^Y$, there is a uniform weak Borel reduction of $E_{\{\psi_i\}}^Y$ to $E_{\{\phi_i\}}^X$.

A related definition will also be of interest to us:

Definition 3.20. Suppose that $E_{\{\phi_i\}}^X$ is a universal countable Borel equivalence relation. Say that $E_{\{\phi_i\}}^X$ is *uniformly universal* if for every $E_{\{\psi_i\}}^Y$, there is a uniform Borel reduction from $E_{\{\psi_i\}}^Y$ to $E_{\{\phi_i\}}^X$.

All known universal and weakly universal countable Borel equivalence relations are uniformly universal and uniformly weakly universal when equipped with natural generating families. For instance, $E(F_2, 2)$ is uniformly universal with respect to the shift action of F_2 , arithmetic equivalence is uniformly universal with respect to the family of arithmetic reductions, and Turing equivalence is uniformly weakly universal with respect to the family of Turing reductions. Note that uniform universality and uniform weak universality both depend on the generating family that we use. In particular, every universal/weakly universal countable Borel equivalence relation E is uniformly universal/uniformly weakly universal for some generating family, as one can see by applying Theorem 3.6.

Question 3.21. *Suppose that $E_{\{\phi_i\}}^X$ is a weakly universal countable Borel equivalence relation. Must $E_{\{\phi_i\}}^X$ be weakly uniformly universal?*

A positive answer to Question 3.21 would provide the characterization of the non-weakly-universal ideal of \equiv_T that is needed so that a positive answer to Question 3.18 implies Borel Martin's conjecture.

Proposition 3.22. *An affirmative answer to both Question 3.21 and Question 3.18 implies Borel Martin's conjecture.*

Proof. In what follows, equip \equiv_T with the generating family of Turing reductions. Consider a \equiv_T -invariant subset B of 2^ω so that $\equiv_T \upharpoonright B$ is weakly universal. Supposing Question 3.21 has a positive answer, there must be a uniform countable-to-one homomorphism from \equiv_T to $\equiv_T \upharpoonright B$. Hence, B must contain a cone.

Now let $f : 2^\omega \rightarrow 2^\omega$ be a homomorphism from \equiv_T to \equiv_T . Supposing Question 3.18 has a positive answer, there is a weakly universal \equiv_T -invariant subset B of \equiv_T and a uniform homomorphism g from \equiv_T to \equiv_T so that $f(x) \equiv_T g(x)$ on B . By the above, B contains a Turing cone. \square

Versions of Questions 3.18 and 3.21 that extend beyond the Borel realm also seem interesting. For instance, one can consider these questions in the context of $\text{ZF} + \text{DC} + \text{AD}^+$, where we use AD^+ as opposed to AD so that there is enough uniformization so that weakly universal countable equivalence relations exist. Here, positive answers to these questions would imply the analogue of Martin's conjecture for the Δ_n^1 degrees and the degrees of constructibility via versions of Proposition 3.22 and Theorems 1.2 and 1.3 for these degree notions.

We finish by stating a question about uniform universality which is related to Question 3.21, and has arisen naturally in other work.

If we generate \equiv_T by the family of Turing reductions, then by applying the uniform case of Martin's conjecture in Theorem 1.2, we see that there cannot be any uniform embedding of $\equiv_T \sqcup \equiv_T$ into \equiv_T . Hence, \equiv_T is not uniformly universal for the generating family of Turing reductions. Montalbán, Reimann, and Slaman (unpublished) have generalized this fact to show that \equiv_T is not uniformly universal when it is equipped with a certain generating group. The central technical obstacle in their work is adapting the game proofs of [25] to work with this group. Montalbán, Reimann, and Slaman posed the question of what role uniformity plays in universality proofs, and more broadly in the theory of countable Borel equivalence relations. Their question has been inspiration for much of this section. In this spirit, we ask the following:

Question 3.23. *Suppose that $E_{\{\phi_i\}}^X$ is a universal countable Borel equivalence relation. Must $E_{\{\phi_i\}}^X$ be uniformly universal?*

Uniform universality in this more general setting has also shown up naturally in recent work of Marks [18], who has shown that many-one equivalence is uniformly universal with respect to the generating family of many-one reductions if and only if a question in Borel combinatorics has an affirmative answer. A resolution of Question 3.23 would help clarify this situation.
